CRUISE OF THE "CARNEGIE"

How would you like to spend the next two years sailing around and around the world on a sailing ship? This is to be the experience of eight men selected by the Carnegie Institution of Washington who sailed last Tuesday (May 1) on the non-magnetic ketch *Carnegie* from the Seventh Street wharf, Washington, D. C. This vessel has already made six voyages during 1909-1921, covering about 220,000 miles, in a magnetic and electric survey of the oceans. She was built entirely of non-magnetic materials—bronze, aluminum, brass and copper being used in her construction instead of iron or steel, since the latter metals cause uncertainties in the use of the instruments used in making the observations.

So, after an interval of over six years, the *Carnegie* is once more the wonder down the latitudes in quest of general scientific information. With her crew of 13 men besides the eight scientists, she will sail to Hampton Roads and Bermuda, and then for Ireland.

As the sun goes southward next fall, the *Carnegie* will work south through the Atlantic, and then proceeding past such well-known South Pacific visiting the Society Islands, Easter Island, and Peru, and coming north again to Japan and California by the end of 1929 or early in 1930. Unless world conditions call for unusual alertness and delays due to stormy weather and to improve the conditions for making her investigations. Among the places to be visited after leaving California are Honolulu, Samoa, New Zealand, Fiji, Australia, Ceylon, South Africa, Ceylon, India, Western Australia; across the South Pacific again and around the Horn to Buenos Aires, Argentina, St. Helena, Azores, and finally back to Washington in September, 1931.

But you must not be too envious of these men, because this is not to be a pleasure jaunt. It is an expedition to be devoted entirely to scientific research work at sea. This means that the members of the crew will not have time even to get seasick. Perhaps you would like to hear who they are going, and what they are to investigate. We shall let Captain Auli, the commander, and chief of the scientific staff, tell about the program. Captain Auli has been in command of the *Carnegie* on three cruises, each of the two latter lasting two years. He says:

Magnetic and Electric Conditions

"First, we are going to find out what the magnetic and electric conditions (magnetic elements) over various ocean areas since the previous cruises of the *Carnegie*. This information is of interest to the student of the earth's magnetism in his study of the many unsolved problems in this science. Also, it is of practical value needed to keep the navigation charts up to date. These charts are used by the air pilot as well as by the sea pilot.

"Among these unsolved problems are the origin of the earth's magnetic field, the cause of the daily and seasonal changes in this field, the close relation between magnetic storms and the sun-spot cycle, the effects and changes in the condition of the sun, and why we have eleven-year periods in magnetic changes and disturbances coincident with the well-known eleven-year sun-spot cycle. Besides helping to obtain the successes of data regarding these changes, it has been planned to continue to a large extent the tracks of former cruises. The causes of these changes and variations are not yet known, and their explanation constitutes one of the most important of the science of terrestrial magnetism.

"The second important investigation will consist of a continuation of study of the earth's electric field. The *Carnegie* has been equipped with apparatus for the collection of data in connection with variations in atmospheric-electricity and variations in magnetic conditions.

"Our information regarding the nature of electricity and constitution of the earth's crust has been greatly made in radio transmission have given added stimulus to these studies. The electric elements which we are to investigate again include the potential gradient—the amount per foot which increases with height above the earth's surface, being about 100 volts at the height of one meter. There are present in the air at all times both positively and negatively charged particles called ions, about 1,000 of each kind in a cubic centimeter of air, or 16,000 to the cubic inch, and very small conductivity. It is possible to count the number of these ions.

"Intimately connected with the number of ions present in the air is its electric conductivity or its ability to carry an electric current. Whether penetrating radiation, or "cosmic rays" coming into the earth's atmosphere from outer space can be one of the causes of ionization of the air which increases its conductivity is another of the problems to be investigated.

"The amount of radio-active materials, such as radium and thorium, present in the earth's crust is to be measured, this being another cause of ionization. These investigations show that, under normal conditions, there is everywhere an electric current flowing from the air to the earth. There is not enough of this current, however, to operate anything but a toy motor and we need never fear electrocution from this cause.

Radio Transmission Problems

"Recent investigations of variations in the earth's magnetic field, and in magnetic and electric conditions have led us to install a very complete radio equipment on the *Carnegie* for the first time. Short wave broadcasts will be received during the entire cruise and a definite program of time signals and messages has been arranged with the Naval Research Laboratory in Washington. Thus we will carry out experiments and investigations on the important problems of radio transmission, as well as those in signal reception. Time signals will be received daily, thus aiding to the accuracy of our time-keeping and consequently to the reliability of our navigation and charts.

"The accuracy of our knowledge of finally unknown expanse of atmosphere above the earth's surface and of the equally unexplored depths of the ocean, is likened by the late Lord Kelvin of Langley or the inventive imagination of a Lord Kelvin. When investigation is carried to the point where the conditions of the earth's atmosphere due to change in altitude, many new and important discoveries will be made.

"The deep-sea scientific program has to be investigated is known as oceanography, and we shall confine our attention to the physical and biological phases of this science. This is a new field of research for the *Carnegie*.

"In spite of the considerable amount of information which has been accumulated by the various expeditions since the famous British cruise of the *Challenger* (1872 to 1876), we have only a general idea of the contours of the ocean bed, and only a meager knowledge of the bottom sedimentary deposits which are of peculiar interest to us in the study of the age and formation of the earth and the changes which time has wrought in the mapping of the configuration of the great basins covering over two-thirds of the earth's surface should be as important as the mapping of the land masses which occupy less than one-third. Such information will be useful in the study of movements within the earth's crust and of the origin, history and future development of submarine earthquakes.

"We have installed one of the recently perfected sonic depth-finders, and we can determine in a few minutes the depth of the ocean as the vessel is proceeding on her course. The method consists of measuring the time necessary for a sound signal to be sent out from the ship, travel to the bottom of the ocean, and the echo to return to the ship again. Sound travels at the rate of about 4,800 feet, a little less than one mile, per second, so that if the time between the sending of the signal and the receipt of the echo is one second, the depth is about 4,800 feet.

The Saltness of the Sea

"Some corrections in this assumed velocity are necessary on account of varying conditions of temperatures and salinity, or salt content of the water, but we expect to make these corrections by means of tables. Variations in levels from the surface down to the bottom. We have limited ourselves to four miles of wire only as the bottom of the sea will be out of reach of the sounding wire. Soundings in greater depths are miles by means of depth yet measured by wire, the record being near the Philippine Islands.

"Water samples and temperatures will be secured by Nansen reversing bottles and deep-sea reversing thermometers sent down to various levels, in bottles being used on the wire at the time the sounding is made. Samples of the ocean water supply will be determined immediately on board the ship.

"Ocean currents and salinity in its vast bodies of water cause interesting movements which, combined with other relative movements due to the earth's rotation, have a great influence capacity for carrying heat a powerful factor in its influence upon practically every phase of life upon the earth, in its control of climate, and in the distribution of certain man's migrations and habitations.

"Samples of muds and sediments from the bottom will be secured by use of various devices sent down on the wire. One consists of a tube or sampler resembles the jaws of a turtle and is sent down open. When it strikes the bottom a spring catch is released and a specimen is snapped up into the tube. Another device, a tube is forced into the bottom mud by a lead weight and a specimen of the bottom mud long is brought up, the lead weight which forced the tube into the bottom released and left on the bottom. It is now known that bottom living creatures of a benthonic nature are found in bottom muds, and that these muds are often teeming with life. From a study of these organisms and their relation to the food supply, ranges from oil wells, important conclusions have been reached regarding the origin of oil-producing deposits.

The "Grass of the Sea"

"Perhaps the most fascinating study of the ocean is that of the vast and indicuous life found in all oceanic waters from the surface down to the deepest abyss yet explored. Physical and chemical changes in the ocean-waters have profound influence upon the life found in them, both in distribution and in distribution. A knowledge of these influences will contribute in many ways not only to the study of evolutionary processes taking place in the sea but also to the practical problem of the economic use of the ocean's food supply.

"The problems in marine biology are so many and so far-reaching that it has been necessary to confine our attention to a few of the most important, to determine the abundance and distribution of the so-called "grass of the sea," the plankton, and other small organisms such as diatoms, copepods, and foraminifera, which constitute the food supply of fishes.

"Sick sea-cats of various sizes, dip-nets, and tow-nets will be used to collect these organisms. A special double boat beam, called by the men a bob, will be provided to rather plankton has been rigged so that we can walk on the water for 30 feet from the ship's stern, perhaps with more faith than we should have if we were to study the surface organisms or operate the surface nets. We shall study the disturbing influences of the ship and its motion through the water, and will make use in part of our experience, so that in warm, clear, tropical waters we may determine at what depth below the surface among the fishes learn how they live and study and determine the wonders of the underwater world.

Conditions Affecting Climate

"A more extensive program of investigation in meteorology is being planned, in view of the importance of fluence upon climate of such movements of large bodies of heat-bearing water. The study of these and the physical interchange of heat and moisture between the ocean and the atmosphere and the air above it is important in the study of atmospheric circulation and the distribution over the entire surface of the earth because of the fairly normal conditions which exist at sea.

"Variation in the amount of solar heat received at the earth's surface and the influence of such variations have been studied by many scientists, notably the study of climatic study in recent years. It has been planned, while in India each day observations by our meteorological program, to make a determination of cloud systems, rainfall, evaporations, dust-content and carbonic-acid gas in the atmosphere. Increased data of these kinds over the great oceans, as well as increased during this 110,000 mile cruise of the *Carnegie* may be extremely valuable in the comparison of results of weather with solar variation, in the determination of the extent to which atmosphere is being charged with water vapor as vital to life on the continents, and in the study of the dynamics of atmospheric circulation over the oceans.

The Staff of Scientists

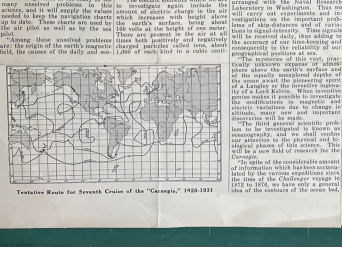
And so last Tuesday morning (May 1) the *Carnegie* left her berth at the 25 tons rigged quietly out into the Potomac, bound on a three-year cruise which is hoped will add much of permanent value to our knowledge of the earth and of the forces which will ultimately will be applied to the improvement of mankind.

The scientists who have been selected to make the investigations are:

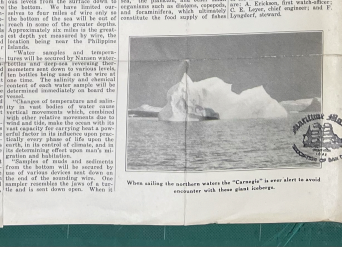
Captain J. F. Auli, commander, and chief of scientific staff.
Wilfred C. Parkinson, senior scientific officer (atmospheric electricity and observer).
Oscar W. Torresen, navigator and magnetician (magnetic observations).
Harry W. Fisher, (magnetician).
F. M. Soule, observer and electrical engineer (magnetic and physical oceanography).
Lyle Taylor, assistant and biologist, (oceanography).
J. H. Paul, surgeon and observer (medical work, meteorology, and oceanography).
Alfred Johnson, engineer (navigation and observer).
Lawrence A. Jones, radio operator and observer (radio conditions and communication).

The institution is fortunate in again having obtained the services of three officers of the sailing staff who were on board during the entire two years of the last cruise of the *Carnegie*, viz., Capt. Auli, first; Wilfred C. Lyons, chief engineer; and F. Lyngdorf, steward.

Captain Auli on the deck of the "Carnegie" inspecting the electrically operated non-magnetic winch which is equipped to reach a depth of 20,000 feet. The line was specially manufactured in Germany of aluminum-bronze which is also non-magnetic.



Tentative Route for Seventh Cruise of the "Carnegie," 1928-1931



When sailing the northern waters the "Carnegie" is ever alert to avoid encounter with these giant icebergs.
